Abstract

Overconfidence is a well-established bias in which someone's subjective confidence in their own judgments is systematically greater than their objective accuracy. There is abundant anecdotal evidence that overconfident people increase their exposure to risk. In this paper, we test whether overconfident people underestimate the probability of incurring an avalanche accident. An avalanche accident is a typical "black swan" event because it has a low probability of occurring but has potential dramatic consequences. To test whether the overconfidence bias affects the decision of backcountry skiers to go on a ski trip under different levels of avalanche risk, we measured individual cognitive traits and then used a random effect logit model to measure their effects on the probability to take the tour, by controlling for other observable characteristics of the respondent. We show that 1) overconfidence is widespread even in our sample and 2) practitioners who are more prone to overestimate their knowledge are also more likely to take the risk associated with a ski trip exposed to avalanche danger. This suggests that overconfident people are more exposed to black swan events.

1. Introduction

A black swan event is something unexpected and unpredictable at the time it occurs, with a dramatic impact on those exposed to it (Taleb, 2007). Some events, such as avalanches, manifest themselves as tragic black swan events, due to their dramatic severity and their rarity. Traditionally, much attention was devoted to risk analysis and risk management aspects both in experimental research and in education programs. Only in recent years, the contribution of human factors to accidents began to assume a growing relevance, focusing researchers' and educators' attention on cognitive aspects such as overconfidence, haste, inexperience and complacency (Furman et al. 2010; Schimelpfenig, 2003).

The aim of the present research is to explore how overconfidence (OC), and other cognitive factors, behaviourally affect decisions under the threat of black swan events.

OC is generally defined as the difference between how much one thinks she knows (confidence) and how much one actually knows (accuracy) (Lichtenstein and Fischhoff, 1977; Ronis and Yates, 1987; Fischhoff et al., 1977; Lichtenstein et al., 1982). Since the seminal work by Lichtenstein and Fischhoff (1977) a large number of studies have examined OC (for reviews see Klayman et al., 1999; Moore and Healy, 2008). The interest for this cognitive trait in the scientific community is well represented by Plous (1993): "No problem in judgment and decision making is more prevalent and more potentially catastrophic than overconfidence".

The original meaning of the term OC was closely related to calibration and probability judgment research. In psychology, individual calibration capacity is usually measured on the basis of general knowledge questions: participants have to answer a set of questions and then to assess the probability that their answers are correct. Well-calibrated individuals are those who are able to correctly assess their amount of mistakes. Miss-calibration phenomena appear when an individual is not able to correctly assess her amount of mistakes. Notwithstanding, the meaning of the term has frequently been stretched beyond its original definition. In some research fields, OC is considered a sign of other cognitive traits or biases, and its original definition has been extended to the context of positive illusions, especially to the better-than-average effect (Svenson, 1981), to the unrealistic optimism (Weinstein, 1980) and to the illusion of control (Langer and Roth, 1975). OC has been advocated as a potential explanation for real world decisional failures, contributing to market bubbles, financial collapses, policy failures, and costly wars (Camerer and Lovallo, 1999; Johnson, 2009; Johnson and Tierney, 2011; Malmendier and Tate, 2005; Tuchman, 2011), but this cognitive trait has been studied mostly in lab experiments (see for example Fischhoff et al., 1977; Cheng, 2007) with little attention in determining its role on shaping real world decisions. One exception is represented by the investigation of the role of OC in pathological gambling domain, where it has been shown to lead to deficits in decision-making (Goodie, 2003; Camchong et al., 2007; Hudgens-Haney et al., 2013).

In the present study, we adopted the original definition of OC in terms of miss-calibration, and we measured OC in a domain-independent task in order to investigate the role of a general cognitive trait, instead of one that is strictly related with individual expertise. In addition, we collected data on those positive illusions that have been traditionally associated to mis-judgments of risk. In particular, we measured the self-reported illusion of control (Langer, 1975; Langer and Roth, 1975; Zuckerman et al., 1996) and unrealistic optimism (Weinstein, 1980). Illusion of control refers to individuals' tendency to believe one can control, or at least influence, outcomes that are clearly

governed by chance and, thus, uncontrollable (Taylor and Brown, 1988; Langer, 1975). Unrealistic optimism, also known as optimistic bias, is the tendency to show an unrealistic optimism toward the future, thinking that negative events will happen less likely to the individual than to the fellow other, while positive events will happen more likely to the individual than to the fellow other (Weinstein, 1980).

Self-reported risk taking in the recreational domain (Weber et al., 2002; Blais and Weber, 2006) was also included in the present research. It assesses how much the individual declares that she will likely engage in a series of risky recreational activities (such as rafting, paragliding, etc.).

Being related to the accuracy and the reliability of individual judgments, OC, and the other cognitive traits described above, might presumably influence individual decisions to expose oneself to dangerous situations. An excessive confidence in our own judgments, along with a great confidence in our knowledge and our capacities, an illusionary feeling of control over the situation, a feeling that only positive event can occur to us, and the tendency to seek for risky situations, can expose us to more hazards, also when specific risk indicators and warnings are present.

Winter mountaineering is a paradigmatic field to test the effect of OC on the decision making process. In fact, the consequence of the decision may be the very life of the skier. The case of backcountry skiers (BS) features all the elements identified by the literature as key ingredients to the insurgence of a decision in which OC plays a role. First, the objective evidence available to the BS is far from compelling. In fact, it normally takes the form of a Weather&Avalanche (WA) report[1], which, in most instances, only provides the BS with a general overview of the level of avalanche risk in the area. This is insufficient to state with a reasonable degree of certainty, whether or not a specific slope would collapse under the BS herself. To a large extent, the decision is not driven by the objective evidence. It is rather based on the BS own judgment. Therefore, the degree of confidence the BS has on her own judgement plays a crucial role. Second, as the probability of occurrence of an avalanche accident is small or very small in most instances, the BS is very likely not to have a direct experience of the event. That is, she lacks fast and clear feedbacks to her decisions (Fischhoff et al., 1977). Additionally, when the feedback comes, it is likely to be a fatal one. Lastly, the fact that the probability of the occurrence of an avalanche accident is normally very small might induce the BS to just overlook it (Lichtenstein et al., 1982).

2. Materials and Methods

We asked a sample of BS's to take part into a survey to collect information on their cognitive traits, as well as on their attitude to practice backcountry skiing at alternative degrees of avalanche risk. Then we studied whether cognitive traits are correlated to the decision to take the tour.

The set up of the experiment closely reproduces the way in which winter mountaineers draw their decision on whether to take a tour and which one to choose for the next day. The evening before, sat at their pc, practitioners collect information on snow and

---

[1] Weather&Avalanche report is released on a regular basis by local agencies and describes the conditions of the weather and of the snowpack in a specific area. It also provides a forecast for the coming days.

weather conditions from the WA report, consider a list of options for their ski tour and finally decide.

People willing to take part in the study sent a message to a computerized system to receive via e-mail the codes to enter an on-line questionnaire. Since the procedure fully preserves the anonymity of the respondents there was no way of obtaining their written consent. The protocol has been approved by the *Comitato Etico per la sperimentazione con l'essere umano* of the University of Trento.

Three hundred and four (304) people – mostly backcountry skiers, only few of them using snow-shoes – completed the questionnaire. We excluded twenty-nine respondents from the analyses either because they reported not to be backcountry skiers nor winter hikers; or because they reported to not know any of the tours listed in the questionnaire; or because they reported to be unwilling to ride the easiest tour even in the most favourable weather condition. The final sample included 275 respondents (90% of them are backcountry skiers; see below). The typical respondent was a middle-aged, experienced and skilled male, strongly committed to ski touring, who chooses and engages in the tours together with peers at his same level of experience and skills. Table 1 provides a summary description of the respondents.

The questionnaire is made up of three sections. The first section collects basic information: age, gender, level of mountaineering experience, way of practicing ski touring or winter hiking (how many tours per week, peers' characteristics, who chooses and leads the tour), and the level of understanding of a WA report.

The second section lists three local and very popular ski tours of increasing level of difficulty (MSA to OSA in the Blachère scale), along with three WA reports characterized by a level of avalanche danger ranging from level 2 – Moderate to level 4 – High (the European Avalanche Danger Scale ranges from 1 - Low to 5 – Very High). Respondents were asked on their willingness to engage in each of the three tours in every WA scenarios. In this way, we collected nine hypothetical decisions for each respondent.

The third and last section measures overconfidence, illusion of control, unrealistic optimism, and risk-taking attitude.

Tab. 1: Description of the 275 respondents selected for the analysis.

Age	41
% of male respondents	91
Years of experience	14
% of mountain guides or Italian Alpine Club instructors	30
% of backcountry skiers	90
% of respondents taking *at least* one tour per week	60
% of respondents regularly taking tours with equally experienced partners	60
% of respondents choosing the tour together with the partners	60
% of respondents reporting self-assessed average/high ski-touring ability	50
% of respondents correctly interpreting the keywords of the WA report	70

Overconfidence was assessed following Goodie (2003) asking participants to answer 18 two-alternatives, general-knowledge questions (i.e. not specific to the backcountry ski domain). After each question people were asked to estimate the confidence that the answer was correct on a half-range scale (from 50% to 100%). The OC score for the ith respondent was computed as the difference between her own average confidence over the 18 answers (CONF), and her own percentage of correct answers to the

18 questions (ACC). CONF could range from 50 to 100. ACC could range from 0 to 100 (50 is the lower limit up to random fluctuations). The theoretical range for the OC score goes from -50 (extreme underconfidence) up to 100 (extreme overconfidence). Respondents who exhibit a positive score believe that they know more than what they actually do. Similarly, respondents who display a negative score believe that they know less than what they actually do.

Illusion of Control was measured using the Unrealistic Control Beliefs Scale (Zuckerman et al., 1996), which assesses perceived control over uncontrollable events. The scale comprises 15 items and answers are given on a seven-points scale from "strongly disagree" to "strongly agree". The individual score is evaluated as the average over the 15 items.

Unrealistic Optimism was measured as suggested by Weinstein (1980). Participants are asked to report how much they think they are likely to experience a series of events as compared to some peers of the same gender and age. 34 events among those proposed by Weinstein (1980) were selected, 12 positive and 22 negative. After inverting the scale for the negative events, the individual score was evaluated as the average over the 34 items.

Self-reported risk taking was measured by the recreational sub-scale of the Domain Specific Risk Taking scale (DOSPERT; Blais and Weber, 2006). The DOSPERT scale is designed to assess risk preferences through self-report in five domains. We used only the items pertaining to the recreational domain. The respondent is asked how likely she would engage in each of six risky practices. Answers were given on a seven points scale, from "extremely unlikely" to "extremely likely". The individual score is evaluated as the average over the six items.

2.1 Analysis

Data were analyzed using the Rasch model (Agresti, 2013). Let Y_{ij} be the binary answer provided by the ith respondent to the jth of the nine combinations ski tour/WA conditions (coded as YES=1, NO=0). We modeled it as a function of α_i – the ith respondent individual characteristic representing the largest level of risk she is available to take – and of:

$$-\gamma_j + \varepsilon_{ij}^* \qquad i = 1,275 \quad j = 1,9 \qquad (1)$$

the level of riskiness of the jth combination ski tour/WA condition as perceived by the ith respondent, with ε_{ij}^* being an unobservable random variable which for computational convenience we assume to follow a zero-mean logistic distribution. Note that the quantity in (1) is made up of a component γ_j, which is common to all the respondents, representing the average perceived level of riskiness, and a second component ε_{ij}^*, which is specific to each respondent. The ith respondent accepts the jth combination ski tour/WA conditions – i.e. she takes the risk of going on that tour in those WA conditions – if and only if her perceived riskiness is not larger than the largest level of risk she is available to take, that is, if and only if the following inequality holds:

$$-\gamma_j + \varepsilon_{ij}^* \leq \alpha_i \qquad (2)$$

It follows that, the probability of going on a tour at the average (perceived) level of riskiness γ_j for a respondent with a threshold for risk α_i is:

$$\Pr(Y_{ij} = 1|\alpha_i,\gamma_j) = \Pr(-\gamma_j + \varepsilon_{ij}^* \leq \alpha_i|\alpha_i,\gamma_j) = \Pr(\varepsilon_{ij}^* \leq \alpha_i + \gamma_j|\alpha_i,\gamma_j) = \Lambda(\alpha_i + \gamma_j) \qquad (3)$$

where $\Lambda(.)$ is the logistic cumulative distribution function. The individual specific threshold for risk, α_i, could depend both on observable, x_i, and unobservable, u_i, individual characteristics:

$$\alpha_i = \beta x_i + u_i \qquad (4)$$

where the vector x_i includes the scores for the cognitive and personality traits and all the individual characteristics that we want to control for (see below).

We end up with a random effect logit model (Agresti, 2013):

$$\Pr(Y_{ij} = 1|x_i,\gamma_j) = E_u\{\Lambda(\beta x_i + u_i + \gamma_j)\} \qquad (5)$$

In evaluating the expected value in (5), we assume u to be a zero mean Gaussian distribution, whose variance is estimated along with the other parameters in the model.

Results of the logistic regression, reported in the next section, are presented as the marginal effect (on the probability of skiing the tour) of each explanatory variable (for the binary variables, it is the effect of switching each of them from 0 to 1). In other words, if the rth component of x is a continuous variable, its effect on the ith respondent is given by the partial derivative of (5) with respect to that component :

$$E_u\{\lambda(\beta x_i + u_i + \gamma_j)\}\beta_r \qquad (6)$$

where $\lambda(.)$ is the first derivative of $\Lambda(.)$ with respect to its argument. Table 3 in the next section summarizes the average of the individual marginal effect (6) evaluated across the 275 respondents included in the sample.

2.2 The role of measurement errors

In this section, we focus on the cognitive trait that turns out to be central to our study, i.e. OC. In particular, we explain why, due to measurement errors, the estimate of its effect from the standard logit analysis is biased toward zero. In our study, the bias is rather considerable and deserves an in-depth discussion. A handy correction to this bias emerges as a result of the following argument.

As already explained, the OC score is measured as the average over 18 items of the item-specific difference between the respondent confidence and the respondent accuracy. Following a standard two-way analysis of variance, we let z_{ij}, i.e. the score on the jth item

for the ith subject, to depend on three components: an individual-specific effect, a_i, which is the true level of individual OC whose average is normalized to zero; an item-specific effect, b_j; and a purely random zero average component, v_{ij}:

$$z_{ij} = a_i + b_j + v_{ij} \qquad i = 1,275 \quad j = 1,18 \qquad (7)$$

The item-specific component, b_j, is introduced to account for the degree of suitability of item j to reveal the subjects' overconfidence. There is clear evidence in the data that it varies across items. Let us consider Figure 1. It presents the distribution of the difference between confidence and accuracy, i.e. the OC scores of the 275 individuals in the sample, specific to two polar items out of the 18 used in the questionnaire. Specifically, item A presents a distribution, which features two large peaks at 100 and at 50 (along with a minor one at -50), the former one meaning that a sizeable proportion of respondents believe they are correct (confidence=100), when, in fact, they are not (accuracy=0). On the contrary, item B exhibits the largest peak at 0, i.e. confidence is equal to accuracy to a notable fraction of respondents.

Fig. 1: Distribution of the difference between confidence and accuracy in two polar items
In order to measure a_i as accurately as possible, we can proceed as follows:

$$z_{i.} = a_i + b. + v_{i.} \qquad (8)$$

where the dot stands for the average over the 18 items. $z_{i.}$, the observed OC score, is equal to the true OC score, a_i, plus the measurement error, $v_{i.}$ (plus $b.$ which here plays as the average value of OC). Note that $v_{i.}$ has to be considered as a measurement error, since it does not convey any information on the respondent's OC, but rather it adds noise.

The parameter we would like to estimate is the coefficient on the true OC score in (5), β_a. In addition, to assign a unit of measurement to OC we focus on the effect of a variation as large as one standard deviation, i.e. we should multiply the regression coefficient by the standard deviation of the true OC score, σ_a. Instead, the parameter we are actually estimating is the coefficient on the observed OC score $z_{i.}$, β_z, times its standard deviation, σ_z. The measurement error has an opposite influence on the estimate. On the one hand, it induces an attenuation bias on the estimate of β_a in that:

$$\beta_z = \frac{\beta_a \sigma_a^2}{\sigma_a^2 + \sigma_{v.}^2} \qquad (9)$$

where $\sigma_{v.}^2 = \sigma_v^2 / 18$ is the variance of $v_{i.}$ (for more details, see Wooldridge, 2005). On the other hand, equation (8) implies that the measurement error induces an overestimation of σ_a^2 in that:

$$\sigma_z^2 = \sigma_a^2 + \sigma_{v.}^2 \qquad (10)$$

Therefore, ignoring the role played by the measurement error in the estimate, leads us to obtain that the estimate of $\beta_a \sigma_a$ from the logit regression is affected by a multiplicative attenuation bias:

$$\beta_z \sigma_z = \beta_a \sigma_a \left[\frac{\sigma_a^2}{\sigma_a^2 + \sigma_{v.}^2} \right]^{0.5} \qquad (11)$$

Since both σ_a^2 and σ_v^2 (along with σ_b^2) can be estimated by fitting equation (7) to the data, for the bias to be corrected, it is sufficient to divide the estimated effect of the OC score by the attenuation bias in equation (11).

In the appendix, we show that the multiplicative attenuation bias can be even smaller than the one displayed in equation (11) if we also consider the other explanatory variables included in vector x (in the specific case we are discussing, however, the difference is qualitatively negligible).

Finally, note that since the average OC is slightly positive (see Figure 2) as a result of the measurement error, the proportion of respondents with a negative OC score in Figure 2 – i.e. the proportion of underconfident in the sample – turns out slightly overestimated:

$$Pr(z_{i.} < 0) = Pr(a_i + b. + v_{i.} < 0) > Pr(a_i + b. < 0) \qquad (12)$$

3. Results and Discussion

Figure 2 shows the distribution of OC in our sample. Approximately 53% of the respondents feature a positive value of the score, that is, they are overconfident.

Table 2 presents the hypothetical decisions as reported by the respondents. It displays the expected pattern both over the level of difficulty of the tour and over the degree of avalanche danger.

Table 3 reports the results of the logit regression as the average marginal effect of the explanatory variables on the probability to go on the tours. Both OC and risk taking matter in the decision, while the other two traits, i.e. illusion of control and unrealistic optimism, turn out to be irrelevant. Other things being equal, a one standard deviation increase of the OC score (it is equal to 9.75) induces a 0.0658 increase on the probability to undertake the tour (t-stat=3.14).

Figure 2: Distribution of the overconfidence score in the sample

As already discussed, this estimate could be biased due to the noise brought in by the measurement errors. In the sample, $var\{v_{ij}\}$ is equal to 1261.10, so that, up to sampling error, the variance of the measurement error is:

$$\sigma_{v.}^2 = \frac{1261.10}{18} = 70.06 \quad (13)$$

On the other hand, $var\{z_{i.}\} = 95.096$. This means that accounting for the measurement error (and up to sampling error), the variance of the true OC score is:

$$\sigma_a^2 = 95.096 - 70.06 = 25.03 \quad (14)$$

implying that 73.67% of the observed variability of the OC score, $z_{i.}$, is due to the measurement error:

$$\frac{\sigma_{v.}^2}{\sigma_{z_i}^2} = \frac{70.06}{95.096} = 0.7367 \quad (15)$$

Therefore, up to sampling error, the attenuation bias in (11) turns out to be as large as:

$$\left[\frac{\sigma_a^2}{\sigma_a^2 + \sigma_{v.}^2}\right]^{0.5} = \left[\frac{25.03}{25.03 + 70.06}\right]^{0.5} = 0.51 \quad (16)$$

Taking this into account, the estimated value of the effect of a one standard deviation increase of OC is as large as:

$$\frac{0.0658}{0.51} = 0.1283$$

In other words, moving from an individual in the left tail of the distribution of the true OC score – percentile 2.5, say – to an individual in the right tail of the same distribution – percentile 97.5, say - the probability of undertaking a tour increases approximately by 0.50 ($0.1283 * 2 * 1.96$; for convenience, here we refer to the Gaussian distribution).

The risk taking score induces an increase in the probability to undertake the tour of the same order of magnitude as OC (but the effect is slightly nonlinear). However, there is a crucial difference in how these two traits may be detrimental for the BS. In fact, while BS's – and mountaineers in general – know they are taking some risk and accept it – i.e. they are aware they are risk takers, they are not at all aware of their own OC and how it influences their decision-making in the avalanche domain. This way, they end up exposed to the black swan with a probability larger than the one they attribute to the event. In the context of the decisions taken by an overconfident practitioner, the substantial lack of awareness undermines all the efforts made by Snow & Avalanche services to forecast more and more accurately the avalanche risk.

Concerning the control variables included in the regression, it is worth to note that a) the effect of the age at which respondents have been taught is correlated positively with the probability to undertake the excursion: ten additional years (meaning that respondents started later in life to practice backcountry ski) implies an increase in the probability by as much as 0.05; b) mountain guides and Alpine Club instructors are less prone to take risks associated with ski mountaineering: other things being equal, the probability to undertake the tour is 0.12 lower; c) the effect of having a direct knowledge of the tour is positively correlated: for those who did it in the past the probability to undertake the tour is 0.1 larger; d) subjects who choose the excursion jointly with their mates are 0.13 more likely to undertake the tour.

4. Robustness checks

In this section we assess the robustness of our results to two possible misspecifications of the analysis. First, there is clear evidence in our data that ACC, the proportion of right answers to the 18 questions is negatively correlated to OC. If ACC had an effect on the decision of the backcountry skier – more cultured respondents might be less prone to take risk, say - omitting it from the regression would result in a biased estimate of the effect of OC. As an extreme case, the positive effect we found for OC might be entirely due to the

effect of the omitted ACC. To check it we re-estimated the logit regression including ACC as an additional regressor. The associated coefficient turns out to be statistically zero.

Second, and at least partly related to the previous issue, by the way in which OC is defined, at high values of ACC there is very little – or not at all - room for overconfidence. That is, to uncover the possible overconfidence of respondents featuring a high ACC score with respect to the 18 items we selected, an alternative choice of more difficult items should be administered to them. Note that this mechanical consequence of the definition of OC might account at least partly for the negative correlation we observe between OC and ACC. To assess whether it affects our estimate, we re-estimated the logit regression excluding from the sample the respondents in the upper tail of the distribution of ACC. The estimated value of the effect of OC turns out virtually unaffected by this reshaping of the sample.

5. Conclusions

In this study, we explored how overconfidence and other cognitive factors affect the individual decision to undergo a backcountry skiing tour exposed to the risk of avalanche. We show that 1) overconfidence is present and widespread in the sample and 2) practitioners more prone to overestimate their knowledge are also more likely to take the risk associated to a ski trip exposed to the avalanche danger. In other words, '…our decisions can be influenced by factors that have nothing to do with the situation, let alone objective facts. What makes those factors insidious is that for the most part we are unaware of the "illogic" of our own thinking' (Larson, 2006).

Our results are surely of interest to BS's. A wrong assessment of the stability of a snow slope unavoidably leads to an avalanche accident. To make things worse, experience, which could in principle help the overconfident BS to better ponder her decisions, operates in the opposite direction, exacerbating the problem. According to the Bayesian updating model developed by Anwar and Loughran (2011), upon receiving new information the rational subject updates her prior beliefs on her own ability to draw an appropriate decision by evaluating a weighted average of the prior belief and of the new information. In the light of this, a BS, who successfully completes a number of tours, could erroneously revise upward the beliefs on her own ability. This way disregarding that, given the low probability of occurrence of an avalanche accident, a long sequence of successful outcomes is not necessarily the result of the BS ability, but may occur purely by chance. Unfortunately, a consistent finding in cognitive psychology is that people tend to take too much credit for their successes and too little responsibility for their failures (Fiske, 2007). As applied to a case in which the probability of experiencing a negative event is low or very low, the consequences of this self-enhancing attribution bias might be extreme, leading to reinforce – rather than downward revise – the prior.

Despite the dramatic improvements over the last 30 years of the probability to survive an avalanche accident, evidence from the Italian side of the Alps tells that the probability of a fatal outcome is still above 0.15. Finding that OC plays a critical role in the decision of BS's suggests that making them aware of the illogic of their own thinking might be an effective tool to reduce their exposure to the risk.

Our results are of interest also beyond the specific field of inquiry in all instances in which decision making under risk is characterized by a trade-off between a more

rewarding alternative under the threat of a black swan and a less rewarding but safer option.

Appendix A

Here we consider the case in which the explanatory variable affected by measurement errors – the OC score in our case – is included in the regression together with other explanatory variables. The regression coefficient β_a in equation (4) is the marginal effect of a unit variation of the true overconfidence level a_i on α_i, the largest level of risk the i-th respondent is available to take (and by that way on the probability of undertaking the tour) holding the other explanatory variables constant. By holding the other explanatory variables constant the variance of the OC score relevant to equation (10) falls to $\sigma_a^2(1 - R_a^2)$, where R_a^2 is the proportion of the variance of the true OC score explained by the regression on the other explanatory variables included in equation (4).

Clearly, R_a^2 can't be directly measured since the regression of the true OC on the other explanatory variable is not feasible. The feasible regression is the one of $z_{i.}$ – the observable OC score – on the other explanatory variables. Let R_z^2 be the fraction of the variance of $z_{i.}$ explained by this regression. Then the following identity holds:

$$(A1) \quad R_z^2 = \frac{\sigma_a^2 R_a^2}{\sigma_a^2 + \sigma_{v.}^2}$$

from which we recover:

$$(A2) \quad R_a^2 = \frac{R_z^2(\sigma_a^2 + \sigma_{v.}^2)}{\sigma_a^2}$$

This way we recover the multiplicative attenuation bias as:

$$(A3) \quad \left[\frac{\sigma_a^2(1 - R_a^2)}{\sigma_a^2(1 - R_a^2) + \sigma_{v.}^2}\right]^{0.5}$$

In the case of the regression of the observable OC score $z_{i.}$ on the other explanatory variables results are those in Table A1.

The R^2 of this regression is as large as 0.086, definitely a very low value. But this is driven by the large variance of the measurement error on the OC score. By taking it into account as in $(A2)$ the R^2 of the regression of the true overconfidence on the other explanatory variables turns out as large as:

$$R_a^2 = \frac{0.086\,(25.03 + 70.06)}{25.03} = 0.33$$

Finally, the attenuation bias resulting from $(A3)$ turns out as large as:

$$\left[\frac{25.03\,(1 - 0.33)}{25.03\,(1 - 0.33) + 70.06}\right]^{0.5} = 0.4395$$

just marginally lower than the one previously found.

Tab. A1: OLS regression of the OC score on the other explanatory variables included in the logit regression.
